

AUTOMATION AND OPTIMIZATION OF COAL GRINDING BY MEANS OF BALL MILLS

PISTUN, Y.; ZAGRAJ, V.; NYKOLYN, H. & FEDORYSHYN, R.

Abstract: *This work deals with the system for automated control and optimization of the technological process of solid material grinding by means of ball mills, which are being applied at heat power stations for grinding the coal, at cement plants for grinding the clinker and at ceramic plants for grinding the clay. The developed system provides continuous monitoring of the grinding, ventilating and drying productivities and it optimizes the mill performance in order to reach the maximum possible grinding productivity. Application of the system provides safe operation of the mill in automatic mode, reduction of specific energy consumption for grinding a unit weight of the solid material (by 5 to 30 % depending on the type of the mill) as well as considerable increase of the grinding productivity of the mill. The system was installed at a number of heat power stations for grinding the coal and it provided significant positive technological and financial benefits to the power generating companies.*

Key words: *ball mill, grinding, automation, optimization, efficiency*

1. Introduction

The technological processes of solid material grinding by means of ball mills are of great importance for many branches of industry. They are of particular importance for efficient operation of heat power stations consuming coal as the energy carrier, for cement plants where clinker is grinded, for ceramic plants where clay is grinded and for other plants. A specific feature in running a ball mill is that the grinding mills are big power consumers, since grinding process is power-intensive. The electric power consumption for solid material grinding amounts up to about 20 % of the total power consumption for own needs of the plant or about 2 % of the total amount of power produced by the heat power station (Levit, 1991).

A ball mill consists of a cylindrical steel drum (with the size of 2 to 5 m in diameter and 3 to 15 m in length) and steel balls (up to 25 cm in diameter) inside of it. The drum is being rotated by means of an electric drive (with power consumption of up to 1 MW). The raw material is fed into the mill at the inlet side of the drum by means of a feeder and the grinded material is taken away at the outlet side of the drum by means of the ventilation system. This is how grinding in a ball mill takes place (Perov, 1990).

The relation between grinding productivity and loading of a ball mill by the material is proportional. The more material is fed into the mill the higher grinding productivity. But at some point there is too much material in the mill and the material is not grinded any more, the grinding productivity decreases abruptly down to zero and the mill blockage takes place (see Fig. 1). Depending on the properties of the solid material and on characteristics of the dust system, the mill blockage may take place at various loadings of the mill. This is an emergency situation and it should be avoided.

Fig. 1. Grinding productivity of a ball mill versus loading of the mill with the solid material

2. Peculiarities of Ball Mill Automation

The process of solid material grinding in ball mills has been automated poorly, because there were no methods to measure the main parameters of the grinding process, such as amount of the material in the mill, grinding productivity and especially there were no methods to determine the pre-failure condition in which the mill is so much overloaded with the material being ground that it leads to abrupt decrease in its grinding productivity and to blockage. In order to prevent the failure of a mill the operators deliberately decrease the grinding output by feeding less material to the mill, which makes the grinding process more power-intensive and less efficient (Levit, 1991). There were no reliable methods to find the optimal loading of a mill in order to reach the maximum possible grinding productivity.

Many investigators, however, with a purpose of ball mill automation, have carried out experimental studies and established relations between the main technological parameters of the grinding process and a number of indirect indexes (Touil et al., 2006; Shuvalov et al., 2009). Based on these studies, various schemes for automation of ball mills have been proposed: to regulate the outlet temperature of the air mixture, to regulate the differential pressure across the mill drum and to regulate the acoustic signal of the mill. But all those systems could not ensure the maximum possible grinding productivity and they did not prevent a possible blockage of the mill.

The maximum possible grinding productivity depends on the properties of the solid material (grain composition, grinding ability index, rock concentration, moisture content etc.), on the characteristics of the dust system (drying ability, ventilating ability and grinding ability), on the amount of material fed into the mill and on the feeding system and its regime (Formusatin, 2010).

The main companies dealing with automation of grinding processes are Siemens, Schenk, Brüel&Kjær and other. A great deal of attention is paid by these companies to automation of roller mills and less attention is paid to automation of ball mills. Another specific feature is that the existing ball mill automation systems do not provide optimization of ball mill loading in order to reach maximum grinding productivity.

The experience of using the systems developed earlier has put forward the task to improve them and to create new algorithms for calculation of actual values of the main technological parameters of the grinding process, including a new method to measure the amount of material in the mill. Another task was to develop new algorithms in order to optimize mill performance both under standard conditions and under constraints on drying ability and ventilating ability of the dust system [6]. It was also necessary to take additional measures to provide safe operation of the mill and to try out failure situations. In order to fulfill all the above tasks a ball mill automation and optimization system was developed.

3. Description of the Developed Ball Mill Automation System

The structural diagram of the developed ball mill automation and optimization system is shown on Fig. 2. A piezoceramic accelerometer is mounted on the front bearing of the mill and it measures the vibration acceleration of the mill bearing. This signal correlates directly with the mill loading with the material to be ground. Another piezoceramic accelerometer is mounted on the back bearing of the mill and its signal correlates with the quality of the grinding process (fineness of grinding). The interrelation between these parameters is monitored by the controller-optimizer. A temperature transducer is applied to measure the temperature of the air mixture at the mill outlet. A differential pressure transducer is applied to measure the differential pressure across the drum of the mill.

Fig. 2. Structural diagram of the ball mill automation and optimization system: 1 – raw material feeder (RMF); 2 – from separator; 3 – drying agent; 4 – ball mill; 5 – temperature transducer; 6 – differential pressure transducer; 7,8 – piezoceramic accelerometers; 9 – controller-optimizer; 10 – to separator.

During operation of a ball mill it is especially important to avoid the exceeding of the maximum limiting temperature of the air mixture, which can result in an explosion of the dust system. Therefore the developed ball mill automation system provides a mechanism to prevent overheating of the air mixture. A sound alarm is provided to give a signal of a pre-failure situation with a possibility to interrupt the supply of a heating agent. In order to safeguard the dust system the precautionary measures are taken by the automation system to avoid the temperature going out of the specified range and to avoid the exceeding of the maximum limiting value of the differential pressure across the mill drum.

According to a specially developed algorithm the controller of the automation system adjusts automatically to the existing dust system, grinding ability of the mill and to the qualitative properties of the material being ground. As these parameters vary the controller adjusts automatically to regulate the material feeding so that the grinding productivity is always maximal. When there are constraints in the dust system on drying ability, ventilating ability or maximum temperature of the air mixture at the mill outlet the material is fed in such a way that the temperature of the air mixture at the mill outlet is maintained within the specified limits and the differential pressure across the mill drum does not exceed the maximum limiting value.

The task of the main operation mode of the controller-optimizer is to ensure such a feeding of raw material into the mill at which the maximum possible grinding productivity is reached and the ball mill operates on the peak of the curve of grinding productivity (see Fig. 1). The controller-optimizer switches to other modes when there are constraints on the mill's drying ability or ventilating ability, as well as when the pre-failure situations occur. When the system goes outside of the limiting conditions, the controller-optimizer switches to the dynamic optimization mode in search for an optimal loading of the mill by the material.

When there are no constraints on the drying ability and ventilating ability of the mill and when there is no pre-failure situation the controller-optimizer operation mode is determined by the relative degree of mill loading. So when the relative degree of mill loading is less than 40%, the material is fed into the mill continuously at the maximum possible productivity of the feeder. In other cases the material is fed into the mill according to a special algorithm until the maximum value of loading degree is reached. As soon as the optimal value of the mill loading is reached, when the dust system operates at the maximum possible productivity, the controller-optimizer maintains this value as long as the technological process conditions do not change.

The productivity of raw material feeder should be 1.5 - 2 times higher than the mill's grinding productivity. This is the main condition to ensure normal running of the technological process of material grinding in the mill. When the feeder productivity is insufficient, the controller-optimizer operates in a non-standard mode which is characterized by a lower degree of mill loading. This, in turn, results in an inefficient operation of the dust system.

Insufficient drying ability and ventilating ability of the mill are also limiting factors for reaching the maximum possible grinding productivity of the mill. When such constraints occur optimization of mill operation is possible only within the specified constraints.

4. The Main Features of the Developed Ball Mill Automation and Optimization System

The developed ball mill automation and optimization system provides accomplishment of the following tasks:

- Measurement and calculation of three main technological parameters: loading degree of the ball mill with the material being ground, air mixture temperature at the mill outlet and the differential pressure across the mill drum.
- Optimization of the grinding process including continuous search and maintaining of the ball mill loading degree by regulating the feeding of solid material into the mill in order to ensure the maximum possible grinding productivity of the mill.
- Continuous monitoring of drying ability and ventilating ability of the dust system, and in case of decrease of these parameters down to critical values – optimization of mill operation within allowable constraints.
- Dynamic optimization of the grinding process when the system is switched from the modes with specified constraints or from unloaded condition to optimal loading mode.
- Visualization of controller operation modes, current values of the mill loading degree, the air mixture temperature at the mill outlet and the differential pressure across the mill drum, as well as minimum and maximum limits of the air mixture temperature and the differential pressure across the mill drum.
- Signalization of work and stops of raw material feeder, occurrence of constraints on dust system drying ability and ventilating ability, exceeding of the maximum limiting temperature value of the air mixture, existence of pre-failure situations.
- Prevention of mill blockage by the material being ground.
- Guarantee of safe operation of the dust system in automatic mode.

One more feature provided by the developed ball mill automation and optimization system is protection of the electric drive of the mill. If the drive is overloaded the system will switch it off in order to prevent the break-down of the drive.

The ball mill automation and optimization system (Fig. 3) was developed by scientists of Lviv Polytechnic National University together with experts from “Techprylad” Research and Design Production Company (Lviv, Ukraine). We are working in the field of automation of industrial processes and automation of ball mills in particular for more than 20 years.

5. Implementation of the Developed Ball Mill Automation and Optimization System

The developed automation and optimization system was installed at a number of ball mills at heat power stations for grinding the coal, at cement plants for grinding the clinker and at ceramic plants for grinding the clay.

One of the systems was installed at a heat power station where three ball mills were used to grind the coal for a 300 MW power generating unit. Application of the developed ball mill automation and optimization system provided raising of grinding productivity of the mills in such a way that the productivity of two mills was enough for preparation of the fuel for the power generating unit and the third mill was turned off. This is how energy saving by 30 % at coal grinding was reached.

Fig. 3. Some elements of the developed ball mill automation and optimization system

Another system was installed at a heat power station for automation of two ball mills for coal grinding. The total grinding productivity of the mills was 20 tons per hour. After installation of the system the total grinding productivity of the two mills increased up to 23 tons per hour and pauses in operation of each mill were provided which resulted in significant saving of electric energy.

Thanks to the developed ball mill automation and optimization system the technological and financial benefits are provided to the companies where ball mills are applied for solid material grinding. The main technological benefits are in reduction of the electric power consumption, increase in grinding productivity and improvement of reliability at ball mill operation. The financial benefits are in spending less money for grinding a unit weight of solid material due to the increased grinding productivity and the reduced power consumption. The payback period for the system is 1-1.5 years.

6. Conclusion

A new ball mill automation and optimization system is developed. Application of the system provides improvement of the main parameters of the technological process of solid material grinding by means of ball mills, which are being applied at heat power stations for grinding the coal, at cement plants for grinding the clinker and at ceramic plants for grinding the clay.

Implementation of the system ensures a considerable increase in grinding productivity of a ball mill irrespective of the quality characteristics of the material being ground and irrespective of the condition of the dust system. It also consumes less power per unit weight of the material being ground.
